The authors have declared that no conflict of interest exists.

Cells isolated from patients with ataxia telangiectasia are exquisitely sensitive to ionizing radiation. Kinase inhibitors of ATM, the gene mutated in ataxia telangiectasia, can sensitize tumor cells to radiation therapy, but concern that inhibiting ATM in normal tissues will also increase normal tissue toxicity from radiation has limited their clinical application. Endothelial cell damage can contribute to the development of long-term side effects after radiation therapy, but the role of endothelial cell death in tumor response to radiation therapy remains controversial. Here, we developed dual recombinase technology using both FlpO and Cre recombinases to generate primary sarcomas in mice with endothelial cell–specific deletion of Atm to determine whether loss of Atm in endothelial cells sensitizes tumors and normal tissues to radiation. Although deletion of Atm in proliferating tumor endothelial cells enhanced the response of sarcomas to radiation, Atm deletion in quiescent endothelial cells of the heart did not sensitize mice to radiation-induced myocardial necrosis. Blocking cell cycle progression reversed the effect of Atm loss on tumor endothelial cell radiosensitivity. These results indicate that endothelial cells must progress through the cell cycle in order to be radiosensitized by Atm deletion.

Introduction

Approximately 50% of all cancer patients receive radiation therapy at some point during the course of their illness (1). Despite recent advances in treatment planning and delivery, normal tissue toxicity often limits the ability of radiation to control tumors locally. However, targeted drugs have the potential to increase the probability of tumor eradication by selectively sensitizing tumor cells to radiation (2, 3). Ataxia telangiectasia mutated (ATM) is a serine/threonine protein kinase that senses DNA double-strand breaks and phosphorylates several key proteins to initiate the DNA damage response, leading to cell cycle arrest, DNA repair, or apoptosis (4, 5). Cells isolated from patients with ataxia telangiectasia, which lack functional ATM, are exquisitely sensitive to ionizing radiation (6). Based on this observation, ATM inhibitors have been developed to sensitize tumors to radiation therapy (7, 8). Although these inhibitors have been shown to radiosensitize tumor cell lines and xenografts (9), concern over radiosensitization of normal tissues may limit their clinical application. For example, we previously demonstrated that cell type–specific deletion of the ATM phosphorylation target p53 sensitizes mice to radiation-induced gastrointestinal injury (10) and myocardial necrosis (11). Although Atm-knockout mice have been used to study acute radiation injury, these mice are tumor prone (12, 13). Therefore, this model cannot be used to investigate the long-term consequences of blocking ATM during focal radiation therapy.

Human cancers develop in a complex environment composed of blood vessels, fibroblasts, and immune cells. The tumor microenvironment contributes to cancer development, progression, and response to therapy (14). However, it remains controversial whether stromal cells, such as endothelial cells, can be targeted by radiosensitizers to enhance the efficacy of radiation therapy (15–17). It has been reported that deletion of Atm in endothelial cells impairs the development of tumor vasculature and slows the growth of transplanted melanoma cell lines (18). However, transplanted tumor models may not fully recapitulate the vasculature of autochthonous tumors (19). To clarify the function of endothelial cell ATM in tumor development and radiation response, and also to investigate the long-term consequences of blocking ATM in normal tissues treated with focal radiation therapy, we have developed novel dual recombinase technology to mutate Atm specifically in the endothelial cells of primary tumors (20). Our findings demonstrated that loss of Atm in endothelial cells did not affect tumor initiation or growth of primary soft tissue sarcomas. However, deletion of Atm specifically in proliferating tumor endothelial cells increased radiation-induced endothelial cell death and delayed tumor regrowth after radiation therapy. In contrast, deletion of Atm in quiescent cardiac endothelial cells did not sensitize mice to radiation-induced myocardial necrosis. Although loss of Atm radiosensitized p53-null endothelial cells in vitro and tumor endothelial cells in vivo, radiosensitization was reversed by treatment with a cyclin-dependent kinase inhibitor. These results suggest that the effect of Atm loss on radiosensitivity depends on the state of cellular proliferation.
Figure 1. Dual recombinase technology enables VE-Cadherin-Cre to delete Atm in primary sarcoma endothelial cells. (A) Recombinase expression in KPFRT; VE-Cadherin-Cre mice injected with adenovirus FlpO to generate sarcomas. (B) Reporter expression in KPFRT; VE-Cadherin-Cre; mTmG mice. All cells initially express tdTomato, and VE-Cadherin-Cre deletes tdTomato and turns on eGFP expression in endothelial cells (green). (C) Fluorescence images of CD31-stained soft tissue sarcomas initiated with adenovirus FlpO in KPFRT; VE-Cadherin-Cre; mTmG mice in the absence of radiation (No IR) and 2 weeks after irradiation with 20 Gy. Images are representative of 3 mice per group. (D) Representative immunofluorescence images of a sarcoma in a KPFRT; LSL-eYFP mouse initiated with adenovirus Cre and stained with GS-IB4. (E) Genetic strategy to activate Kras and delete p53 in tumor cells and delete Atm in endothelial cells. Control mice retained 1 WT allele of Atm in endothelial cells. (F) Expression of Atm mRNA in FACS-isolated tumor endothelial cells (CD45 CD34 CD31) from the indicated mice (n = 3 per group). (G) and (H) Immunofluorescence (G) and quantification (H) of CD31+ pATM+ cells in sarcomas from KPFRTVAtmfl/+ and KPFRTVAtmfl/fl mice 4 hours after irradiation with 20 Gy (n = 4 per group). A pATM+ endothelial cell in the KPFRTVAtmfl/fl mouse (arrows) and a pATM+ endothelial cell in the KPFRTVAtmfl/fl mouse (arrowheads) are shown at higher magnification in the insets. Data are mean ± SEM. Scale bars: 100 μm (C, D, and G); 25 μm (G, insets) *P < 0.05.

Results
Deletion of Atm in endothelial cells of primary tumors. It has recently been reported that Atm is activated in the endothelial cells of transplanted melanomas, and that deletion of Atm in endothelial cells decreases tumor angiogenesis and slows tumor growth (18). To investigate ATMs activity in the endothelial cells of primary soft tissue sarcomas, we generated sarcomas in conditional LSL-KrasG12D; p53fl/fl mice (referred to herein as KPFRT; ref. 21) and collected unirradiated tumors and tumors 4 hours after irradiation of the sarcoma with 20 Gy (Supplemental Figure 1A; supplemental material available online with this article; doi:10.1172/JCI73932DS1). We selected 20 Gy for our studies because this dose of radiation has been previously reported to trigger radiation-induced endothelial cell death in normal tissues (22) and tumors (15). 20 Gy is also a radiation dose used in the clinic to treat cancers with radiosurgery or stereotactic body radiation therapy. We stained sections from these tumors with antibodies against the endothelial cell surface marker CD31, ATM phosphorylated at Ser1987 (pATM), and KAP1 phosphorylated at Ser824 (pKAP1), as KAP1 is phosphorylated by ATM in response to DNA damage (23). Consistent with the previous report in transplanted melanomas (18), we detected ATM activation in unirradiated sarcoma endothelial cells. In addition, pATM and pKAP1 levels in tumor endothelial cells were significantly increased after 20 Gy focal irradiation (Supplemental Figure 1, B–E).

To investigate the role of ATM in the endothelial cells of primary tumors, we used dual recombinase technology to initiate sarcomas in conditional FSF-KrasG12D; p53fl/flKPFRT (referred to herein as KPFRT) mice with an adenovirus expressing FlpO (adeno-FlpO) (20) and deleted Atm in a mouse with an adenovirus expressing CreO (Adeno-flpO) (20) and deleted Atm (Figure 1A and ref. 25). We evaluated the efficiency of Cre-mediated recombination in tumor endothelial cells by crossing KPFRT; VE-Cadherin-Cre mice to membrane-Tomato/membrane-GFP (mTmG) reporter mice (26). In mTmG mice, cells expressing Cre are labeled with enhanced GFP (eGFP), and cells that do not express Cre are labeled with tdTomato protein (Figure 1B). To determine whether eGFP is expressed in tumor endothelial cells from KPFRT; VE-Cadherin-Cre; mTmG mice, we stained sarcomas with the endothelial cell markers CD31, VE-Cadherin, and CD34 and the myeloid cell marker CD11b. The majority of eGFP-expressing cells also expressed the endothelial cell markers, and very few myeloid cells expressed eGFP (Figure 1C and Supplemental Figure 2, A–C).

To confirm that tumors initiated by intramuscular injection of adenovirus only have Kras and p53 mutated in tumor cells, we generated sarcomas with an adenovirus expressing Cre recombinase in KPFRT mice with a Cre-activated eYFP reporter (LSL-eYFP) (27). Staining with Griffonia simplicifolia-IB4 lectin (GS-IB4) to label endothelial cells (28) and macrophages (29) confirmed that tumor cells had recombined the eYFP reporter, while the stromal cells were not infected by the adenovirus (Figure 1D).

To evaluate the efficiency of deleting the Atm allele in primary sarcoma endothelial cells with VE-Cadherin-Cre, we generated sarcomas in KPFRT; VE-Cadherin-Cre; Atmfl/fl (referred to herein as KPFRTVAtmfl/fl) mice and in control KPFRTVAtmfl/fl littermates, which retain 1 WT allele of Atm in endothelial cells (Figure 1E). We isolated endothelial cells from sarcomas in KPFRTVAtmfl/fl and KPFRTVAtmfl/fl mice by fluorescence-activated cell sorting (FACS) (Supplemental Figure 2D) and measured Atm mRNA levels by quantitative real-time RT-PCR (qRT-PCR). Tumor endothelial cells from KPFRTVAtmfl/fl mice had significantly less Atm mRNA than tumor endothelial cells from KPFRTVAtmfl/fl controls (Figure 1F). In addition, pATM and pKAP1 levels were significantly reduced in CD31+ cells after 20 Gy focal irradiation of primary sarcomas in KPFRTVAtmfl/fl mice (Figure 1, G and H, and Supplemental Figure 2, E and F), which suggests that VE-Cadherin-Cre functionally deletes Atm in sarcoma endothelial cells.

We next investigated the effect of Atm deletion in tumor endothelial cells on tumor initiation and growth. In contrast to transplanted melanomas (18), there was no change in primary sarcoma initiation or sarcoma growth after deletion of Atm in endothelial cells (Figure 2, A–C, and Supplemental Figure 3, A–C). Moreover, microvascular density and tumor hypoxia in primary sarcomas were not affected by deletion of Atm in tumor endothelial cells (Figure 2, D–G, and Supplemental Figure 3, D and E), demonstrating that Atm in endothelial cells is not essential for angiogenesis in primary soft tissue sarcomas.

Loss of Atm sensitizes tumor endothelial cells to radiation therapy. To determine the effect of Atm deletion in endothelial cells on tumor radiation response, we irradiated sarcomas in KPFRTVAtmfl/fl and KPFRTVAtmfl/fl mice with a single dose of 20 Gy using fluoroscopy-guided radiation therapy. Deletion of Atm significantly increased the number of dead endothelial cells 24 hours after radiation therapy, as indicated by CD31 and TUNEL double staining, but did not affect endothelial cell apoptosis 4 hours after radiation therapy (Figure 3, A and B, and Supplemental Figure 4A). In addition, loss of Atm in endothelial cells increased the total number of TUNEL+ cells within the sarcoma at 24 hours after irradiation (Figure 3C), which suggests that endothelial cell death in primary sarcomas may trigger death of adjacent cells. Because the timing of endothelial cell death in sarcomas from KPFRTVAtmfl/fl mice was consistent with mitotic catastrophe, and because cells undergoing mitotic catastrophe can trigger the cellular apoptotic

(B) Tumor growth curves and (C) time to tripling for unirradiated sarcomas in KPFRT/VAtm⁶/⁶ and KPFRT/VAtm⁶/⁰ mice (n = 10 per group). (D and E) Immunofluorescence (D) and quantification (E) of endothelial cell marker CD31 in sarcomas from KPFRT/VAtm⁶/⁶ and KPFRT/VAtm⁶/⁰ mice (n = 10 per group). (F and G) Immunofluorescence (F) and quantification (G) of hypoxia marker EF5 in sarcomas from KPFRT/VAtm⁶/⁶ and KPFRT/VAtm⁶/⁰ mice (n = 10 per group). Regions of low and high hypoxia are shown for both genotypes. All data are mean ± SEM. Scale bars: 100 μm (D and F).

To investigate functional changes in tumor vasculature after radiation, we imaged sarcomas in KPFRT/VAtm⁶/⁶ and KPFRT/VAtm⁶/⁰ mice using fluorescence molecular tomography (FMT) with AngioSense, a blood pool imaging agent (31). Prior to irradiation and 24 hours after treatment with 20 Gy, AngioSense was injected intravenously, and the concentration of accumulated probe within each sarcoma was measured after 24 hours. In contrast to tumors in KPFRT/VAtm⁶/⁶ mice, which had an increase in AngioSense accumulation after irradiation, AngioSense accumulation decreased in tumors from KPFRT/VAtm⁶/⁰ mice (Figure 3, E and F), suggestive of decreased vascular function. To determine whether the increased radiation-induced endothelial cell death in tumors from KPFRT/VAtm⁶/⁰ mice decreased blood flow to tumors, we injected Hoechst 33342 intravascularly and quantified tumor perfusion. Hoechst 33342 perfusion was significantly decreased in sarcomas from KPFRT/VAtm⁶/⁰ mice 24 hours after irradiation with 20 Gy (Figure 3G and Supplemental Figure 4C).

All data are mean ± SEM. *P < 0.05. Scale bars: 100 μm (A); 25 μm (A, insets).
Similar to the results with a single 20 Gy treatment, KPFRTVAtmfl/fl tumors had a significantly longer growth delay after fractionated radiation (Figure 3, J and K). These findings further indicated that Atm deletion sensitizes tumor endothelial cells to radiation in vivo and demonstrated that endothelial cell death can contribute to the growth delay of primary tumors after radiation therapy.

Deletion of Atm in endothelial cells does not sensitize mice to radiation-induced myocardial necrosis. Damage to the vasculature of the heart after irradiation precedes pathological changes to the myocardium and contributes to radiation-induced cardiac injury (32). In response to ionizing radiation, ATM activates the transcription factor p53 through several mechanisms to stabilize p53 mRNA and protein (5), which leads to increased transcription of p53 target genes, including the cyclin-dependent kinase inhibitor p21. p21 is required for the radiation-induced G1 cell cycle checkpoint and for a sustained G2 checkpoint in some cells (33). Because we previously demonstrated that p21-null mice or mice with VE-Cadherin-Cre-mediated deletion of p53 are sensitized to radiation-induced myocardial necrosis within 4 months of 12 Gy whole-heart irradiation (11), we hypothesized that VAtmfl/fl mice would also succumb to myocardial necrosis after whole-heart irradiation. To confirm that VE-Cadherin-Cre deletes Atm in heart endothelial cells, we isolated endothelial cells from VAtmfl/fl and littermate control VAtmfl/+ mice by FACS and measured Atm mRNA levels by qRT-PCR. Cardiac endothelial cells from VAtmfl/+ mice had significantly less Atm mRNA than did cardiac endothelial

Figure 4. Deletion of Atm in p53 WT endothelial cells does not sensitize mice to radiation-induced myocardial necrosis. (A) Kaplan-Meier plots of myocardial necrosis-free survival for VAtmfl/+, VAtmfl/fl, VPfl/+Atmfl/+, and VPfl/+Atmfl/fl mice after 12 Gy whole-heart irradiation. (B) Kaplan-Meier plots of myocardial necrosis-free survival for VAtmfl/+, VAtmfl/fl, VPfl/+Atmfl/+, and VPfl/+Atmfl/fl mice after whole-heart irradiation with 10 daily fractions of 3 Gy. 1 VPfl/+Atmfl/fl mouse died prior to finishing irradiation and was censored. (C) Kaplan-Meier plots of myocardial necrosis-free survival for VPfl/+Atmfl+ and VPfl/+Atmfl/fl mice after 8 Gy whole-heart irradiation. Mice of both genotypes were censored due to development of thymic lymphomas prior to heart disease. (D–I) Representative sections of the myocardium of (D–F) a VAtmfl/fl mouse 463 days after whole-heart irradiation and of (G–I) a VPfl/+Atmfl/fl mouse 56 days after whole-heart irradiation, subjected to staining with H&E (D and G) or Masson trichrome (E and H) or immunofluorescence for WGA, TUNEL, and GS-IB4 (F and I). *P < 0.05. Scale bars: 100 μm (D–I).
cells from VAtm/fl+ mice (Supplemental Figure 5A). We then irradiated VAtm/fl+ and VAtm/fl− mice with 12 Gy whole-heart irradiation and monitored them for development of myocardial necrosis (Supplemental Figure 5B). In contrast to tumor endothelial cells, deletion of Atm in heart endothelial cells did not increase the number of dead endothelial cells 24 hours after irradiation (Supplemental Figure 5, C and D).

Next, we irradiated VAtm/fl+ and VAtm/fl− mice with a single dose of 12 Gy or 10 daily fractions of 3 Gy whole-heart irradiation and monitored them for development of myocardial necrosis (Figure 4, A and B). Remarkably, mice with deletion of Atm in endothelial cells did not die until 15 months after 12 Gy whole-heart irradiation (Figure 4A). Histopathological examination of the heart and lungs from both VAtm/fl+ and VAtm/fl− mice demonstrated focal regions of myocardial fibrosis and extensive pulmonary fibrosis, but no evidence of myocardial necrosis, after both single-dose and fractionated radiation exposure (Figure 4, D–F, and Supplemental Figure 6, A–H, M, and N). We did not observe any coronary atherosclerosis by histology after whole-heart irradiation of VAtm/fl+ or VAtm/fl− mice.

To confirm that the difference in endothelial cell radiation sensitivity between tumors and hearts was not due to a difference in radiation dose, we also irradiated VAtm/fl+ and VAtm/fl− mice with 20 Gy whole-heart irradiation. There was no difference in overall survival between the 2 genotypes (Supplemental Figure 7A). Histopathological examination demonstrated pulmonary hemorrhage and inflammation after 20 Gy whole-heart irradiation in both VAtm/fl+ and VAtm/fl− mice, but no evidence of myocardial necrosis (Supplemental Figure 7, B–E).

Because VE-Cadherin-Cre; p53fl/fl mice are sensitized to radiation-induced myocardial necrosis, as a control, we next investigated whether loss of Atm in endothelial cells could further sensitize these mice to radiation-induced heart disease. We irradiated VE-Cadherin-Cre; p53fl/fl; Atmfl/fl (referred to herein as Vp53fl/fl; Atmfl/fl) mice and Vp53fl/fl; Atmfl/fl littermate controls with 10 daily fractions of 3 Gy or a single dose of 12 or 8 Gy whole-heart irradiation and monitored them for myocardial necrosis development. Vp53fl/fl; Atmfl/fl mice exhibited significantly accelerated development of myocardial necrosis compared with Vp53fl/fl; Atmfl/fl mice after all radiation exposures (Figure 4, A–C). Histopathological examination of hearts from both Vp53fl/fl; Atmfl/fl and Vp53fl/fl; Atmfl/fl mice showed multifocal myocardial necrosis (Figure 4, G–I, and Supplemental Figure 6, I–L). These results suggested that Atm deletion sensitizes p53-null cardiac endothelial cells, but not cardiac endothelial cells with intact p53, to radiation therapy.

To determine whether deletion of Atm in endothelial cells affects cardiac function after whole-heart irradiation, we performed echocardiography of VAtm/fl+ and VAtm/fl− mice prior to irradiation and 6 weeks and 1 year after whole-heart irradiation with 12 Gy. In contrast to mice with p53 deleted in endothelial cells, which developed systolic dysfunction within 2 months after whole-heart irradiation (11), VAtm/fl+ and VAtm/fl− mice maintained normal cardiac function 6 weeks after irradiation (Figure 5, A–D, and Supplemental Table 1). At 1 year after whole-heart irradiation, both VAtm/fl+ and VAtm/fl− mice began to develop cardiac dysfunction, manifest by decreased fractional shortening, increased left ventricular mass, and increased left ventricular end-systolic...
VAtm<sup>fl/+</sup> and VAtm<sup>fl/fl</sup> mice had a markedly elevated respiratory rate (Figure 5E). Taken together with the histological studies, these results suggested that a combination of myocardial and pulmonary fibrosis contributed to the morbidity of VAtm<sup>fl/+</sup> and VAtm<sup>fl/fl</sup> mice. Except for an increased aortic ejection time and a decreased heart rate in VAtm<sup>fl/fl</sup> mice, there was not a significant difference in cardiac function between the 2 genotypes. Consistent with the pulmonary fibrosis observed histologically, both VAtm<sup>fl/+</sup> and VAtm<sup>fl/fl</sup> mice had a markedly elevated respiratory rate (Figure 5E). Taken together with the histological studies, these results suggested that a combination of myocardial and pulmonary fibrosis contributed to the morbidity of VAtm<sup>fl/+</sup> and VAtm<sup>fl/fl</sup> mice.

mice to a similar extent after 1 year. Therefore, deletion of Atm in endothelial cells does not affect the development of myocardial necrosis after whole-heart irradiation.

Loss of Atm sensitizes proliferating, but not quiescent, endothelial cells to radiation. Previous studies in mice demonstrated that deletion of Atm radiosensitizes proliferating normal tissues, such as the intestinal epithelium (12) and skin (34). We observed that although Atm deletion was sufficient to sensitize tumor endothelial cells to radiation, Atm deletion in cardiac endothelial cells with intact p53 was not sufficient to sensitize mice to radiation-induced myocardial necrosis. Therefore, we hypothesized that the proliferative status of the endothelial cells might affect the impact of Atm loss on radiosensitivity.

Previous studies have shown that tumor endothelial cells proliferate much more rapidly than endothelial cells in normal tissues (35, 36). To determine whether endothelial cells proliferate more in primary sarcomas than in the heart, we compared the cell cycle distribution of endothelial cells in hearts and sarcomas in KPFRTVAtmfl/fl and KPFRTVAtmfl/fl mice. In primary sarcomas, we observed significantly more endothelial cells in the S and G2-M phases and significantly fewer endothelial cells in G0-G1 compared with endothelial cells in hearts (Figure 6, A and B). In addition, BrdU pulse-chase analysis demonstrated that unlike heart endothelial cells, which did not undergo successive cell divisions within 48 hours, BrdU+ tumor endothelial cells reentered the cell cycle within 24 hours (Supplemental Figure 8A). Deletion of Atm in endothelial cells did not affect the baseline proliferation of sarcoma or heart endothelial cells (Figure 6C and Supplemental Figure 8B). However, unlike sarcoma endothelial cells in KPFRTVAtmfl/fl mice, those in KPFRTVAtmfl/fl mice did not undergo cell cycle arrest after irradiation (Figure 6C). Taken together with our finding that deletion of Atm sensitized tumor — but not cardiac — endothelial cells to radiation, these results are consistent with a model in which proliferating endothelial cells are preferentially radiosensitized by Atm deletion.

To explore genes that may regulate the differential proliferation between sarcoma endothelial cells and heart endothelial cells, we performed qRT-PCR on FACS-isolated heart and sarcoma endothelial cells to determine mRNA levels of Atm, p53, p21, Ccnb1, and Ccnb1 (Supplemental Figure 8, C–G). Sarcoma endothelial cells had significantly less p21 mRNA than heart endothelial cells. Interestingly, both heart and sarcoma endothelial cells lacking Atm were able to significantly upregulate p21 after radiation, but the level of p21 mRNA in sarcoma endothelial cells after irradiation with 20 Gy was less than in unirradiated heart endothelial cells (Supplemental Figure 8, H and I).

To more directly assess the impact of proliferation on how Atm deletion affects endothelial cell death following radiation, we isolated primary cardiac endothelial cells from VPfl/flAtmfl/fl and VPfl/flAtmfl/fl mice for in vitro studies (Supplemental Figure 9A). We also attempted to culture endothelial cells from VAtmfl/fl mice (i.e., WT for p53), but primary cardiac endothelial cells without Atm failed to grow well in vitro. Therefore, our in vitro studies focused on p53-null endothelial cells. Cardiac endothelial cells from VPfl/flAtmfl/fl mice were significantly more radiosensitive than those from VPfl/flAtmfl/fl mice, as measured by clonogenic survival and flow cytometry for cell death (Figure 6D and Supplemental Figure 9B). Furthermore, deletion of Atm in cardiac endothelial cells significantly decreased in vitro tube formation and cell migration after irradiation (Supplemental Figure 9, C–F).

To investigate whether blocking cell cycle progression could protect these cardiac endothelial cells from the increased radiation sensitivity of Atm deletion, we treated the cells with the cyclin-dependent kinase 1 (CDK1), CDK2, CDK5, and CDK9 inhibitor SCH727965 (37). SCH727965 treatment for 24 hours significantly inhibited CDK activity, as measured by phosphorylation of retinoblastoma (Rb) (38, 39), and significantly decreased the progression of cardiac endothelial cells from both VPfl/flAtmfl/fl and VPfl/flAtmfl/fl mice into mitosis (Figure 6E and Supplemental Figure 9, G and H). Although vehicle-treated cardiac endothelial cells from VPfl/flAtmfl/fl mice underwent significantly more radiation-induced cell death 24 hours after radiation, there was not a significant change in cell death for cardiac endothelial cells from VPfl/flAtmfl/fl and VPfl/flAtmfl/fl mice treated with SCH727965 immediately prior to radiation exposure (Figure 6F). To determine whether the increased cell death in cardiac endothelial cells from VPfl/flAtmfl/fl mice was due to entry into mitosis with unrepaired DNA damage and subsequent mitotic catastrophe, we quantified micronuclei formation 24 hours after irradiation of cardiac endothelial cells from VPfl/flAtmfl/fl and VPfl/flAtmfl/fl mice with and without SCH727965 treatment. Vehicle-treated cardiac endothelial cells from VPfl/flAtmfl/fl mice had significantly more micronuclei after irradiation with 12 Gy, but there was not a significant change in micronuclei formation for cardiac endothelial cells from VPfl/flAtmfl/fl and VPfl/flAtmfl/fl mice treated with SCH727965 immediately prior to radiation (Figure 6G).

To investigate whether deletion of Atm selectively radiosensitizes proliferating tumor endothelial cells to radiation in vivo, we stained sarcoma sections from KPFRTVAtmfl/fl mice 24 hours after radiation with CD31, TUNEL, and Ki67 to mark proliferating cells (40). There were significantly more TUNEL+ endothelial cells in the Ki67+ population (Figure 6H). Next, we treated tumor-bearing KPFRTVAtmfl/fl and KPFRTVAtmfl/fl mice with vehicle or SCH727965 via intraperitoneal injection. SCH727965 treatment significantly decreased the number of BrdU+ endothelial cells after 24 hours in both genotypes (Figure 6I). To determine whether blocking cell cycle progression could decrease the effect of Atm loss on tumor endothelial cell radiosensitivity in vivo, we quantified sarcoma endothelial cell death 24 hours after treatment of KPFRTVAtmfl/fl and KPFRTVAtmfl/fl mice with vehicle or SCH727965 immediately prior to irradiation of the sarcomas with 20 Gy. Consistent with the in vitro experiments, there was significantly more sarcoma endothelial cell death in KPFRTVAtmfl/fl mice after treatment with vehicle, but not SCH727965 (Figure 6I). Taken together, these results demonstrated that progression through the cell cycle is necessary for loss of Atm to radiosensitize endothelial cells.

Discussion
In this study, we used novel dual recombinase technology to compare the effect of Atm deletion on the response of the same cell type (endothelial cells) to radiation under different physiological states: proliferation and quiescence. We found that deletion of Atm in proliferating tumor endothelial cells enhanced the response of primary sarcomas to radiation, but deletion of Atm in quiescent endothelial cells of the heart did not sensitize mice to radiation-induced myocardial necrosis. Furthermore, blocking cell cycle progression...
reversed the effect of *Atm* deletion on endothelial cell radiosensitivity. These results indicated that endothelial cells must progress through the cell cycle to be radiosensitized by *Atm* deletion.

Previous studies have reported that loss of ATM does not affect the radiosensitivity of all cells and tissues equally. For example, most tissues in *Atm*-null mice appear histologically normal shortly after irradiation, but the rapidly proliferating cells in the intestine display severe radiation toxicity (12, 34, 41). Interestingly, loss of *p21* further sensitizes *Atm*-null mice to radiation-induced gastrointestinal injury (42). Therefore, even in proliferative tissues, loss of cell cycle checkpoints may further increase the effect of *Atm* deletion on radiosensitization. Our present results suggested that the abrogation of cell cycle checkpoints allows quiescent cells to be sensitized to radiation as a consequence of *Atm* deletion. Recently, we reported that cardiac endothelial cells lacking *p53* or *p21* are sensitized to radiation (11). Furthermore, mice lacking *p21* or mice lacking *p53* specifically in endothelial cells were sensitized to radiation-induced myocardial necrosis (11). Here, we found that deletion of *p53* in endothelial cells not only permitted *Atm* deletion to sensitize endothelial cells to radiation in vitro, but also allowed *Atm* deletion to accelerate radiation-induced myocardial necrosis in vivo. Previous studies have reported that *Atm* deletion can sensitize other *p53*-null and *p21*-null cells and tissues to radiation (43, 44). By treating *p53*-null endothelial cells in vitro or sarcoma endothelial cells in vivo with a cyclin-dependent kinase inhibitor at the time of irradiation, we were able to block the cells from undergoing mitotic catastrophe and limit the ability of *Atm* deletion to promote radiosensitivity. Taken together, these observations suggested that cells can be radiosensitized by targeting ATM, either because they are proliferating or because they have lost cell cycle checkpoints. These findings have important implications for combining ATM inhibitors with radiation therapy for treating human cancers, because tumor cells often proliferate rapidly and lack cell cycle checkpoints. Indeed, ATM knockdown or inhibition has been shown to preferentially sensitize *p53*-null tumor cells to radiation or genotoxic chemotherapy (9, 45). Because proliferating normal cells are also sensitized by *Atm* deletion, the therapeutic window for targeting ATM will likely be larger for tumors located in or adjacent to quiescent normal tissues, such as extremity sarcomas and brain tumors.

We observed an increased aortic ejection time following whole-heart irradiation and an approximately 20% decrease in heart rate in mice with *Atm* deleted in endothelial cells. Therefore, even though deletion of *Atm* in endothelial cells did not affect survival or myocardial necrosis after whole-heart irradiation (Figure 4 and Supplemental Figure 7), it is possible that deletion of *Atm* in endothelial cells could have a mild effect on the sinoatrial node after irradiation. However, the relative effect of loss of *Atm* in endothelial cells on heart function after irradiation was much less than its effect on tumor response to radiation therapy. It should be noted that the mice used in this study were healthy and young at the time of whole-heart irradiation, and the effect of *Atm* deletion in endothelial cells on radiation-induced heart toxicity could be different in mice predisposed to develop heart disease. For example, vascular smooth muscle cells proliferate in atherosclerotic vessels (46), and targeting ATM may increase the sensitivity of these cells to radiation. As a result, targeting ATM could conceivably increase heart toxicity in patients with established vascular disease.

In this study, we focused on the effect of *Atm* deletion in endothelial cells on the development of radiation-induced myocardial necrosis. Although we previously showed that endothelial cell damage is sufficient to cause radiation-induced myocardial necrosis (11), it is likely that other cell types can also contribute to radiation-induced heart disease. In addition, the contribution of each cell type may depend on the dose and fractionation of radiation therapy. For example, radiation-induced fibrosis is a complex process that likely involves many different cell types (47). Moreover, the mechanisms of radiation injury likely vary across normal tissues. Therefore, the effect of targeting ATM during radiation therapy should be investigated in all clinically relevant tissues with different radiation doses and fractionation schemes.

In contrast to transplanted melanoma cell lines (18), deletion of *Atm* in the endothelial cells of primary soft tissue sarcomas did not affect vascular development or tumor growth. These discordant results may reflect differences between melanomas and sarcomas or differences in the tumor vasculature between tumors derived from cell lines and autochthonous tumors. Previous studies have demonstrated that the structure, oxygenation, perfusion, and response to therapy of tumor vasculature changes with transplantation (19, 48, 49). Genetically engineered mouse models (GEMMs), such as the soft tissue sarcoma model used in the present study, develop within the native tumor microenvironment in immunocompetent mice (50) and may more faithfully recapitulate the tumor stroma and microenvironment of human cancer compared with xenograft models (51). Additionally, the response of these primary mouse cancer models to therapeutics has been shown to closely model the response of human cancers in clinical trials (52, 53). Taken together, these findings illustrate the importance of studying the tumor microenvironment using multiple complementary models, including GEMMs.

Most GEMMs use Cre recombinase to initiate cancer, making it challenging to simultaneously manipulate genes in tumor stromal cells. In this study, we used FlpO to initiate tumors, enabling VE-Cadherin-Cre to recombine *Atm*-null alleles in endothelial cells. Although FlpO and Cre have been used together previously to sequentially mutate genes in tumor cells (54), this is the first application of dual recombinase technology (FlpO and Cre) to simultaneously mutate genes in both tumor and stromal cells. Combining this dual recombinase technology with the many available floxed alleles and tissue-specific Cre drivers will be a powerful approach by which to investigate the contribution of stromal cells to cancer development, progression, and response to therapy.

It has been reported that endothelial cell apoptosis and microvascular collapse contribute to the response of transplanted tumors to radiation therapy (15). Endothelial cell apoptosis has been reported to be dependent on membrane damage, which triggers rapid ceramide-mediated apoptosis after high doses of radiation exposure (55, 56). In the present study, we did not observe substantial endothelial cell apoptosis at early time points after radiation exposure. Instead, endothelial cell death peaked at 24 hours after radiation in sarcomas from *KIP1RtVAtm* mice and 48 hours after radiation in sarcomas from *KIP1RtVAtm* mice, which suggests that in primary soft tissue sarcomas, tumor endothelial cells die predominantly by a delayed mitotic cell death. Interestingly, the increased endothelial cell death in sarcomas
from \( KP^{RIT}VAtm^{fl/fl} \) mice prolonged tumor growth delay after radiation therapy. Therefore, our results support a model whereby enhanced endothelial cell sensitivity to radiation increases tumor radiation response. We also observed that sarcomas in \( KP^{RIT}VAtm^{fl/fl} \) mice had decreased perfusion after radiation therapy. Although tumors in \( KP^{RIT}VAtm^{fl/fl} \) mice were also sensitized to irradiation with 10 fractions of 3 Gy, it is possible that endothelial cell death may increase tumor hypoxia and thereby decrease the efficacy of subsequent fractions of radiation therapy. Furthermore, an increase in growth delay after radiation therapy does not necessarily translate into improved local control (57–59). To define the contribution of endothelial cells to local control after radiation therapy in this system, future experiments will be required with sarcomas in \( KP^{RIT}VAtm^{fl/fl} \) and \( KP^{RRT}VAtm^{fl/fl} \) mice using higher doses of radiation and local control as the endpoint.

In summary, we found that deletion of Atm sensitized proliferating tumor endothelial cells to radiation and increased the response of primary soft tissue sarcomas to radiation therapy. In contrast, deletion of Atm in quiescent cardiac endothelial cells did not sensitize mice to radiation-induced myocardial necrosis. These results suggest that the state of cellular proliferation determines the effect of Atm deletion on radiosensitivity.

**Methods**

**Mouse strains and tumor induction.** All mouse strains used in this study were described previously, including \( LSL-Kras^{G12D} \), \( p53^{fl/f} \), \( FSF-Kras^{G12D} \), \( p53^{fl/f} \), \( VE-Cadherin-Cre \), \( Atm^{fl} \), \( mTmG \), and \( LSL-eYFP \) (20, 24–27, 54, 60, 61). \( LSL-Kras^{G12D} \) and \( FSF-Kras^{G12D} \) mice were provided by T. Jacks (Massachusetts Institute of Technology, Cambridge, Massachusetts, USA), \( Atm^{fl} \) mice were provided by F. Alt (Harvard Medical School, Boston, Massachusetts, USA), and \( p53^{fl} \) mice were provided by A. Berns (The Netherlands Cancer Institute, Amsterdam, The Netherlands). \( VE-Cadherin-Cre \), \( mTmG \), and \( LSL-eYFP \) mice were obtained from the Jackson Laboratory. Primary sarcomas were generated in the right hind leg of \( KP^{RIT} \) or \( KP^{RRT} \) mice between 6 and 10 weeks of age, as described previously (20, 21). Whole-heart irradiation experiments were carried out with mice between 6 and 10 weeks of age. All mice were on a mixed genetic background. To minimize the effect of genetic background, age-matched littermate controls were used for every experiment so that potential genetic modifiers would be randomly distributed between the experimental and control groups.

**Radiation treatment.** Sarcoma and whole-heart irradiations were performed using the X-RAD 225C x small animal image-guided irradiator (Precision X-Ray). The irradiation field was centered on the target via fluoroscopy with 40 kVp, 2.5 mA X-rays using a 2 mm Al filter. Mice were irradiated with parallel-opposed anterior and posterior fields with an average dose rate of 300 cGy/min prescribed to midplane with 225 kVp, 13 mA X-rays using a 0.3 mm Cu filter. Whole-heart irradiation was performed using a collimator to produce a 15-mm circular radiation field at treatment isocenter. Sarcomas were irradiated at approximately 250 mm³ by caliper measurement using a collimator with a 40 mm x 40 mm radiation field at treatment isocenter. After irradiation, sarcomas were measured 3 times per week until they tripled in size. Endothelial cells were irradiated in vitro with an X-RAD 320 biological irradiator (Precision X-Ray). Cells were placed 50 cm from the radiation source and irradiated with a dose rate of 161 cGy/min using 320 kVp, 10 mA X-rays and a 2 mm Al filter. Dose rates were measured with an ion chamber by the Radiation Safety Division at Duke University.

**Histological analysis.** Sarcoma histology was performed on frozen tissue sections. Tumor and heart frozen specimens were embedded directly in OCT compound (Sakura Finetek) by snap freezing in a dry ice/isopentane slurry and stored at −80°C until sectioning. 10-μm sections were fixed in 4% paraformaldehyde prior to immunofluorescence staining. For intracellular antigens, cells were permeabilized with 0.5% Tween 20 (Sigma-Aldrich). The primary antibodies used were rat anti-mouse CD31 (diluted 1:250; catalog no. 553370, BD Biosciences — Pharmingen), rabbit anti-mouse Ser824-phosphorylated KAP1 (diluted 1:250; catalog no. A300-767A, Bethyl Laboratories), polyclonal rabbit anti-mouse Ser1987-phosphorylated ATM (diluted 1:500; provided by M. Kastan, Duke University Medical Center, Durham, North Carolina, USA; ref. 62), rat anti-mouse VE-cadherin (diluted 1:250; catalog no. 555289, BD Biosciences — Pharmingen), rat anti-mouse CD34 (1:250, catalog no. 553731, BD Biosciences — Pharmingen), rat anti-mouse CD11b (diluted 1:250; catalog no. 14-0112-81, eBioscience), and rabbit anti-mouse CC3 (diluted 1:250; Cell Signaling, catalog no. 9661S). The secondary antibodies used were Alexa Fluor 488-conjugated donkey anti-rat IgG (diluted 1:500; catalog no. A21208, Invitrogen), Alexa Fluor 488-conjugated goat anti-rabbit IgG (diluted 1:500; catalog no. A11006, Invitrogen), Alexa Fluor 555-conjugated goat anti-rabbit IgG (diluted 1:250; catalog no. A21429, Invitrogen), and Alexa Fluor 647-conjugated goat anti-rat IgG (diluted 1:250; catalog no. A21247, Invitrogen). Nuclear staining was performed using Hoechst 33342 (10 μM; Sigma-Aldrich).

Hypoxia was detected using the 2-nitroimidazole agent EF5. 10 mM EF5 in PBS was administered through intraperitoneal injection at a volume of 26.5 μl/g body weight 3 hours prior to euthanasia and tissue collection. EF5 was detected by staining frozen sections with Cy3-conjugated anti-EF5 IgG. EF5 and Cy3-conjugated anti-EF5 IgG were provided by C. Koch (University of Pennsylvania, Philadelphia, Pennsylvania, USA). Perfusion was detected by injecting 20 mg/kg Hoechst 33342 intravascularly 1 minute before tumor excision and snap freezing in OCT.

With the exception of CD31 and TUNEL staining, heart and lung histology was performed on paraffin-embedded tissue sections. Tissue specimens were fixed in 10% neutralized formalin overnight and preserved in 70% ethanol until paraffin embedding. 5-μm sections were deparaffinized with xylene and rehydrated with a graded series of ethanol and water washes prior to performing H&E, Masson trichrome, or immunofluorescence staining. Antigens were retrieved using Antigen Unmasking Solution (Vector Laboratories) according to the manufacturer’s instructions. Wheat germ agglutinin (WGA) and GS-1B4 staining was performed by incubating sections in 5 μg/mL Alexa Fluor 488–conjugated WGA (Invitrogen) and 10 μg/ml Alexa Fluor 647–conjugated GS-1B4 (Invitrogen) for 2 hours at room temperature.

TUNEL staining was performed on frozen sections with the In Situ Cell Death Detection Kit, TMR Red (Roche), according to the manufacturer’s instructions.

Images were acquired with a Leica DFC340 FX fluorescence microscope (Leica Microsystems) using Leica Suite software (Leica Microsystems). Quantification of cells or fractional areas was performed by an observer blinded to genotype and treatment using ImageJ (NIH). Each data point represents the average of 10 randomly selected ×200 fields per sample.
Flow sorting of tumor and heart endothelial cells. Tumors and hearts were dissected, washed in PBS, and homogenized. Tumors were digested in 5 mg/ml type IV collagenase (Gibco) and 1.3 mg/ml dispase (Gibco), and hearts were digested in 0.8 mg/ml type I collagenase (Worthington) for 1 hour at 37°C. Digested tissues were filtered, and red blood cells were lysed with ACK lysing buffer (Lonza). Total number of cells was counted by Coulter counter (Beckman Coulter), 3 × 10⁶ cells were stained with PE-conjugated anti-mouse CD31 (catalog no. 102407, Biolegend), PE-Cy5-conjugated anti-mouse CD45 (catalog no. 15-0451, eBioscience) and eFluor 660–conjugated anti-mouse CD34 (catalog no. 50-0341, eBioscience) antibodies. Dead cells were excluded by staining with 7-AAD (BD Biosciences — Pharmingen) and used for RNA isolation.

qRT-PCR. Total RNA was extracted from sorted heart and tumor endothelial cells with the RNAqueous-Micro Kit (Ambion), and reverse transcription was performed with the iScript cDNA Synthesis Kit (Bio-Rad). qRT-PCR was performed using Taqman universal PCR master mix (Applied Biosystems) and TaqMan Gene Expression Assay Mix (Applied Biosystems) for Atm (Mm01177459_m1), p35 (Mm01731290_g1), p21 (Mm00432448_m1), Cond1 (Mm00432359_m1), Ccnb1 (Mm03053893_g1), or Hprt (Mm0446968_m1). Hprt was used as an internal control to correct for the concentration of cDNA in different samples. Each experiment was performed with 3 replicates per sample, and the results were averaged.

Echocardiography and respiratory rate. Transthoracic echocardiography was performed on conscious mice for all groups with a Vevo 2100 high-resolution image system (VisualSonics) as described previously (11). Respiratory rate was counted visually using high-speed video recordings.

Cell cycle analysis of tumor and heart endothelial cells. Mice were injected intraperitoneally with 200 μl of 5 mg/ml BrdU in PBS. After 4 hours or at the indicated time point, tumors and hearts were harvested and dissociated as described above. 3 × 10⁶ cells were stained with PE-conjugated anti-mouse CD31 (catalog no. 102407, Biolegend), PE-Cy5–conjugated anti-mouse CD45 (catalog no. 15-0451, eBioscience), and eFluor 660–conjugated anti-mouse CD34 (catalog no. 50-0341, eBioscience) antibodies. Cells were then fixed in 2% paraformaldehyde overnight at 4°C. Fixed cells were permeabilized using the Cytofix/Cytoperm Fixation/Permeabilization Kit (BD Biosciences — Pharmingen) according to the manufacturer’s instructions. Cells were then incubated in 300 μg/ml DNase I (Sigma-Aldrich) for 1 hour at 37°C followed by staining with a FITC-conjugated anti-BrdU antibody (catalog no. 11-5071, eBioscience) according to the manufacturer’s instructions. Cells were then fixed and permeabilized using the Cytofix/Cytoperm Fixation/Permeabilization Kit (BD Biosciences — Pharmingen) and analyzed with FlowJo (Tree Star Inc.).

Primary endothelial cell culture. Cardiac endothelial cells were isolated as described previously (11) and cultured in DMEM with 25 mM HEPES and 2 mM L-glutamine (Gibco) supplemented with 20% FBS, 100 μg/ml heparin, antibiotic-antimycotic, nonessential amino acids, sodium pyruvate, and 100 μg/ml endothelial cell growth stimulant (Bio-medical Technologies) on cell culture dishes coated with 0.1% gelatin (Sigma-Aldrich). The purity of cardiac endothelial cells was assessed by flow cytometry with FITC-conjugated anti-mouse CD31 (catalog no. 11-0311, eBioscience) and PE-conjugated anti-mouse CD105 (catalog no. 12-1051, eBioscience) antibodies. Cardiac endothelial cells from passage 1–4 after purification were used for experiments.

Clonogenic survival, tubule formation, and cell migration. For clonogenic survival assays, cells were plated in triplicate and allowed to adhere overnight prior to irradiation. After development of colonies, cells were fixed with 70% ethanol, stained with Coomassie Brilliant Blue (Bio-Rad), rinsed with deionized water, and dried. Populations of >50 cells were counted as 1 colony, and surviving fractions were calculated relative to unirradiated controls.

FMT. Baseline angiogenesis accumulation was measured prior to irradiation by injecting 150 μl Angiosense 680EX (Perkin Elmer) via tail vein injection. After 24 hours, mice were imaged with an FMT2500XL (Perkin Elmer) molecular imaging device using the 680 nm laser channel. Accumulated angiogenesis within the sarcoma was quantified using TrueQuant Imaging Software (Perkin Elmer) and normalized to normal muscle in the contralateral limb. 24 hours after irradiation of the sarcoma with 20 Gy, mice were re injected with Angiosense 750EX (Perkin Elmer) and imaged after 24 hours using the 750 nm laser channel to quantify the change in angiogenesis accumulation.

SCH727965 treatment. Primary cardiac endothelial cells at 60% confluence were treated with DMSO or 500 nM SCH727965 (Selleckchem) for 24 hours. Cells were harvested and fixed with cold 70% ethanol, then stained with rabbit anti-mouse phosphorylated histone H3 (pHH3) primary antibody (diluted 1:500; catalog no. ab5176, Abcam) followed by Alexa Fluor 488–conjugated goat anti-rabbit IgG (diluted 1:1,000; catalog no. A11008, Invitrogen). DNA content was determined by staining cells with 50 μg/ml propidium iodide. Flow analysis for phosphorylated Rb was performed using rabbit anti-Rb phosphorylated at Ser807 and Ser811 primary antibody (diluted 1:400; catalog no. 8516S, Cell Signaling) and Alexa Fluor 488–conjugated goat anti-rabbit IgG secondary antibody to stain primary cardiac endothelial cells fixed and permeabilized using the Cytofix/Cytoperm Fixation/Permeabilization Kit (BD Biosciences — Pharmingen) according to the manufacturer’s instructions.
For radiation experiments, cells were treated with DMSO or 500 nM SCH727965 immediately prior to radiation and harvested at 24 hours for analysis of cell death by flow cytometry or micronuclei quantification. Relative cell death or micronuclei formation was quantified by normalizing irradiated cells to unirradiated cells of the same genotype and drug treatment. Data were collected by FACSCanto (BD Biosciences—Pharmingen) and analyzed with Flowjo (Tree Star Inc.). Micronuclei were counted as described previously (11). For in vivo experiments, mice were treated with 40 mg/kg SCH727965 in 20% (2-hydroxypropyl)-β-cyclodextran via intraperitoneal injection immediately prior to irradiation.

Statistics. 2-tailed Student’s t test was performed to compare means of 2 groups, and 1-way ANOVA followed by Bonferroni post-hoc test was performed to compare means of 3 or more groups. 2-way ANOVA was performed to examine the interaction between genotype and treatment, followed by Bonferroni post-hoc tests for pairwise comparisons of individual treatments or genotypes. Non-normally distributed data were log-transformed before applying statistical tests. For survival studies, Kaplan-Meier analysis was performed followed by the log-rank test for statistical significance. A P value less than 0.05 was considered significant. All calculations were performed using Prism 5 (GraphPad).

Acknowledgments

We thank Frederick Alt for providing Atm" mice, Tyler Jacks for providing LSL-KrasG12D and F5F1-KrasG12D mice, Anton Berns for providing p53" mice, Michael Kastan for providing antibody against pATM, Howard Rockman for assistance with cardiac phenotyping, and Loretta Woodlief and Lixia Luo for help with mouse care. This work was supported by the National Cancer Institute, NIH (grant nos. F30 CA177220 and R21 CA175839).
